## Abstract

*Developments in Wireless Sensor Networks (WSN) hardware have led to a diversity of sensing devices, ranging from simple, micro-controlled boards to complex, highly integrated sensor-transceiver ICs. While this is a desirable effect, it brings about a question about sensor application portability. The lack of proper abstraction and encapsulation mechanisms at the operating system level often forces developers to re-implement their sensing applications whenever a different sensor, radio or processor is deployed.*

*In this paper we introduce a novel strategy for abstracting WSN hardware, based on the Application Oriented System Design method. The strategy was implemented for the EPOS operating system and consists in providing application programmers with an inflated interface for sensing components — a high-level collection of methods and structures derived from the actual components implemented in the system. This interface can latter be bound to pre-existing components that are adapted on demand at system generation time to fulfill application requirements, thus enabling programmers to code portable sensing applications in spite of the hardware diversity and without significant overhead.*

## 1 Introduction

Wireless Sensor Networks (WSN) hardware is, by its very own nature, heterogeneous and modular. Application-specific requirements drive the entire hardware design, from processing capabilities to radio bandwidth and sensor modules. Even in a same family of sensor nodes (e.g. the Berkeley *motes* family [7, 12]) one can find architectural differences that cannot be trivially abstracted. In this scenario, a sensor application developed for a given platform will seldom be portable to a different one, unless the run-time support systems on those platforms deliver mechanisms that abstract and encapsu-

late the sensor platform in an adequate manner. Indeed, a proper abstraction of sensor platforms becomes a key issue in the face of modern SOC (*system-on-a-chip*) solutions, which integrate micro-controller, radio and sensor modules on single ICs that can usually be configured according to user demands [2, 6, 14]. Table 1 presents characteristics of some representative WSN hardware modules. Architectural differences aside, sensor modules (e.g. temperature, light, motion sensors) present an even wider range of variability. Sensor modules presenting the same functionality often vary in their access interface, operational characteristics and parameters.

A properly designed run-time support system could free application programmers from such architectural dependencies and promote application portability among different sensing platforms. Given a sensing application implemented for a certain platform, there is no strong reason why it should not be reused with another platform that fulfills its requirements (e.g. presence of a certain sensor, non-volatile memory capabilities, etc.). For instance, an operating system could deliver a temperature sensor abstraction that would be instantiated by applications giving a range and scale (e.g. linear, logarithmic, Poisson, user-defined, etc). The system would thus ensure proper behavior independently from the physical sensor that exists in the platform.

In the following sections we present current strategies for handling heterogeneity in *Wireless Sensor Networks* and introduce a novel model based on the *Application Oriented System Design* (AOSD) methodology [3]. AOSD introduces the concepts of *hardware mediators*, and *system abstractions* that implement *scenario independent* system constructs. These abstractions are exported to the application through *inflated interfaces* and adapted according to the applications needs through *scenario adapters*. We introduce the model of *sensing abstractions* used in EPOS, an experimental *application oriented* operating system. We then show that this model is capable of properly abstracting WSN hardware heterogeneity with virtually no overhead and producing a very small system footprint.

## 2 Related Work

Most of the current effort in development of operating systems and hardware abstraction for Wireless Sensor Networks is focused on *TinyOS* [7]. Initially developed by the University of California at Berkeley and now an open-source project maintained by several institutions, it is the most widely used OS for Wireless Sensor Networks. TinyOS was written in NesC [5], a high-level programming language that emulates the syntax and functionality of hardware description languages, and provides components for communication, thread coordination, and, of our special interest, hardware abstraction.

Nonetheless, while implementing a complete and functional hardware abstraction layer, the original TinyOS system presented a series of structural problems that hindered application portability. Each hardware platform had a complete and separate HAL implementation. While it is true that architectural differences between platforms may require separate implementations, system interfaces should remain uniform whenever possible. The original TinyOS did not provide a uniform interface for most high level system abstractions (e.g. sensors, timers, etc.), thus forcing the application programmer to understand the nuts and bolts of the underlying hardware platform and compromising application portability between platforms.

TinyOS tried to solve these problems by introducing a three-tiered hardware abstraction architecture, comprised by a *Hardware Presentation Layer*, a *Hardware Adaptation Layer* and a *Hardware Interface Layer*. The Hardware Presentation Layer is placed directly over the underlying hardware, and *presents* the hardware to the operating system. Components in the Hardware Presentation Layer are unique for each device they present, but may share a common structure. The Hardware Adaptation Layer groups the hardware-specific components into domain-specific models, such as Alarm or ADC Channel. The Hardware Adaptation Layer provides the “best” possible abstraction in terms of effective resource usage, but also tries not to hinder application portability. The Hardware

Interface Layer uses the adapted components to implement platform-independent abstractions. The TinyOS application developer may choose to use any of the available interface levels, trading off application portability and efficient resource usage.

The *Mantis Operating System* [1], developed by the University of Colorado, aims at making the task of programming a sensor network as close as possible to the one of programming a PC. Thus, Mantis OS uses the classical model of multi-layered operating systems, with includes multi-threading, preemptive scheduling, and a network stack. Hardware is abstracted through a *UNIX-like* API of device drivers, with a monolithic hardware abstraction layer.

While it is true that the classical OS structure used in Mantis OS may lower the learning curve for novice sensor network developers familiar with an *UNIX-like* system, it is uncertain whether this model translates well to such resource-restricted hardware as sensor nodes. The minimal hardware requirements for Mantis OS are small when compared to classical embedded operating systems [10], they may be too restrictive for tiny devices.

Higher level abstractions often rely on Virtual Machines that abstract the physical hardware into an ideal Virtual Architecture. An underlying translation mechanism ensures correct operation, regardless of specific physical hardware platform details. Thus even highly efficient Virtual Machine implementations, such as *Maté* [9] introduce overhead into the system. *Maté* introduces a high-level interface that allows programs to be replicated throughout the network, reprogramming the nodes in an energy-efficient way. It also provides a safe execution environment, implementing a user/kernel boundary on devices that lack hardware protection mechanisms. In spite of its advantages, *Maté* suffers from the problems inherent to virtual machines, which are especially critical for highly constrained hardware such as sensor nodes, as practical high level abstractions for Wireless Sensor Networks hardware must make efficient use of the sensor node’s low memory, processing and energy capabilities.

### 3 Application Oriented System Design

In this section we introduce the concepts of *system abstractions* and *hardware mediators* in the context of *Application-Oriented System Design* as efficient, high level, reusable hardware abstraction components for sensor networks. *Application-Oriented System Design* (AOSD) [3] was proposed as a multi-paradigm methodology for software design that makes use of several programming and software engineering techniques that can be combined in order to generate run-time support systems configured and optimized for specific applications. The EPOS operating system was implemented following AOSD techniques, and has since been successfully used in several environments [4, 13].

The main goal of the EPOS system is to allow application programmers to write architecture-independent applications, and, through the application analysis, deliver run-time support that complies all the resources that specific application needs, and nothing else. In order to achieve these goals, EPOS relies on the concepts of *Inflated Interfaces*, *System Abstractions*, *Scenario Aspects*, *Configurable Features*, and *Hardware Mediators*. EPOS makes use of *Static Meta programming* and *Aspect-Oriented Programming* techniques to implement software components, thus conferring them a significant advantage over the classic approaches of VMs and HALs. From the definition of the scenario in which the component will be deployed, it is possible to adapt it to perform accordingly without compromising its interface nor aggregating useless code.

#### 3.1 Hardware Mediators

*Hardware mediators* are proposed as software constructs that mediate the interaction between operating system components, called *system abstractions*, and hardware components. The main idea behind hardware mediators is not building universal hardware abstraction layers and virtual machines, but sustaining the “*interface contract*” between system and machine.

Differently from ordinary HALs, hardware mediators do not build a monolithic layer encapsulating the resources available in the hardware platform. Each hardware component is handled via its own mediator, thus granting the portability of abstractions that use it without creating unnecessary dependencies. Hardware mediators are intended to be mostly meta programmed and therefore dissolve themselves in the abstractions as soon as the interface contract is met. In other words, a hardware mediator delivers the functionality of the corresponding hardware component through a system-oriented interface.

Hardware mediators are organized in families whose members represent the significant entities in the domain. For instance, a family of CPU mediators would feature members such as ARM, AVR8, and PPC. A simple hardware mediator for the GPIO bus in the AVR processor is presented in figure 2. This mediator abstracts the assembly language operations responsible for reading and writ-

#### Families of Hardware Mediators

Figure 1. A family of hardware mediators.

ing to IO ports into high level C++ operators without any overhead.

#### 3.2 System Abstractions and Inflated Interfaces

AOSD relies on *Scenario-Independent System Abstractions* to implement the operating system components. These components define the system functionalities, and their implementations rely on several techniques such as *Static Meta programming* and *Aspect-Oriented Programming*, allowing these abstractions to be strongly configurable.

System Abstractions are collected from an *Application-Oriented Domain Analysis and Decomposition* process. This analysis process is quite similar to *object-oriented decomposition*. The main difference is that the Application-Oriented System Design is a multi-paradigm design methodology, so other entities, such as aspects and configurable features must come out from this analysis.

Each system abstraction is composed by a set of similar operating system components. These components are organized according to the *Family-Based Design* paradigm, and have their *commonalities* and *variabilities* explored through different class hierarchies. An *inflated interface* exports the family as though a “super” component, that implements all responsibilities assigned to the family. This component is derived from the interfaces of individual family members, and realized through their implementations. In EPOS, the system framework automatically selects interface realizations, taking into account the target hardware configuration and a cost model for components.

```

class AVR8_GPIO_Port:
    protected GPIO_Port_Common {
public:
    enum {
        PORTA = 0x39,
        PORTB = 0x36,
        PORTC = 0x33,
        PORTD = 0x30
    }; // ...
    void operator=(unsigned char value) {
        _ddr = (unsigned char)0xff;
        _port = value;
    }
    operator unsigned char() {
        _ddr = (unsigned char)0x00;
        return _pin;
    } // ...
private:
    IO_Register<unsigned char> _pin;
    IO_Register<unsigned char> _ddr;
    IO_Register<unsigned char> _port;
    };

```

Figure 2. The AVR\_GPIO hardware mediator

### 3.3 Scenario Aspects and Configurable Features

In AOSD, non-functional aspects and cross-cutting properties are factored out as *scenario aspects* that can be applied to family members as required. For instance, families like UART and Ethernet must often operate in exclusive-access mode. This could be achieved by applying a share-control aspect to the families.

*Configurable features*, on the other hand, designate features of mediators that can be switched on and off according to the requirements dictated by abstractions. A configurable feature is not restricted to a flag indicating whether a preexisting hardware feature must be activated or not. Usually, it also incorporates a *Generic Programmed* [11] implementation of the algorithms and data structures that are necessary to implement that feature when the hardware itself does not provide it. An example of configurable feature is the generation of CRC codes in an Ethernet mediator.

## 4 EPOS Sensing Components

The main goal of the EPOS system is to allow application programmers to write architecture-independent applications, and, through the application analysis, deliver run-time support that complies all the resources that specific application needs, and nothing else. In order to match its goal, EPOS relies on the *Application Oriented System Design* (AOSD) [3] method to guide the development of system abstractions as families of software components, each of which implements a *scenario-independent abstraction* that can latter be adapted to a given execution scenario with the aid of *scenario adapters*. Software components

are collected in a repository and are exported to the application programmers via *inflated interfaces*, which hide the peculiarities of each member in a family as though the whole family was a component. This strategy, in addition to drastically reducing the number of exported abstractions, enables programmers to easily express their application’s requirements regarding the operating system.

In order to preserve the portability of its software components, EPOS relies on hardware mediators. In principle, none of EPOS’s abstractions interact directly with the hardware, utilizing the corresponding hardware mediators instead. In this way, a context switch done in the realm of a Thread abstraction concerns mainly the decision of which thread should occupy the CPU next, leaving the operation of saving and restoring the CPU’s context to the corresponding mediator.

### 4.1 Sensors and Sentients

There are several different architectures of sensors in use today, which makes a hard job to define a common way to access such devices. These devices range from simple, digital integrated circuits to complex and (usually) analog devices.

Devices in the first category are usually simple, digital integrated circuits and are generally implemented over a serial bus (e.g. I2C, SPI). In this kind of sensors, the data acquisition process is initiated by a specific signal or by read and write operations. Another characteristic of these sensors is that there is a regular time period in which new values are sensed. Examples of these sensors are the Texas TMP family of temperature sensors, most Honeywell Magnetometers, the STM Accelerometers and most A/D converters. On the other end, we have very specific and, generally, analog circuits. Examples of this category of sensors are the Berkley’s Mica Sensor Board light and temperature sensors. These sensors share the same analog circuit, making its use and management a complex issue. This circuit is composed by two thermistors and one photo resistor, which are managed through 3 GPIO pins, and deliver their results to the same A/D pin. Even being a simple circuit, it has operation and timing constraints. Another example is the Mica Magnetometer. It is implemented by a complex analog and digital circuit and in spite of being configured by a simple I2C potentiometer, it has an analog output and complex semantics and timing characteristics.

Even with all these differences between sensing hardware, it is possible to affirm that sensor operation does follow a *regular pattern*. This pattern is constituted by an “start sensing” command, followed by an optional configuration phase. Once configured, there is a period of waiting for the sensor’s data acquisition phase. When data acquisition is done, data is finally read. The sensing routine can then be stopped, or may be kept in a “wait acquisition / get data” loop.

In order to contemplate all possible kinds of sensing hardware, EPOS implements the families of mediators and

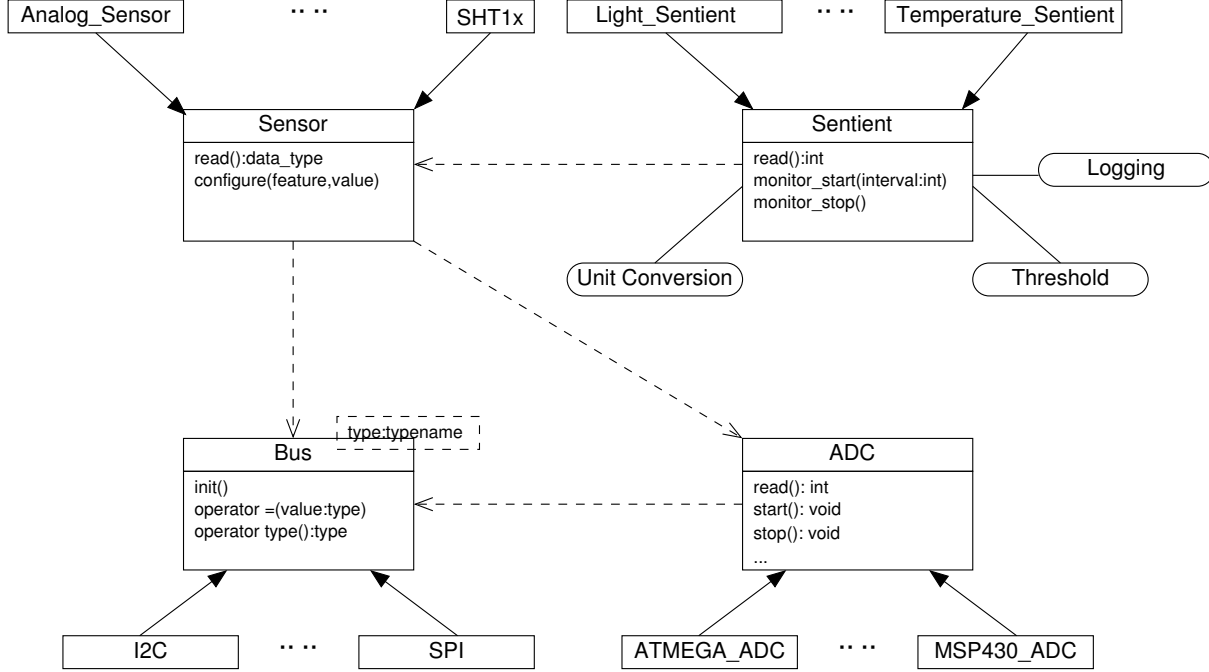

Figure 3. Set of relevant sensing components.

abstractions shown in Figure 3. The *Bus* mediator family of components implements a uniform way to access peripheral devices. The *ADC* family of A/D Converters mediators also implements an uniform access to such devices. These two basic mediators' families are the key to a modular implementation of the EPOS's sensing subsystem, once it allows the *Sensor* family of mediators to be composed by highly configurable and reusable components. Some of the implemented mediators for the *Sensor* family are also shown in the figure. Every other implementation just needs to extend the *Sensor* component and make its hardware dependent implementation.

These hardware mediators structures allow the design of a higher-level, architecture-independent family of abstractions, which can be used by applications without affecting its portability. The *Sentient* family is comprised by software components that aims in abstracting the sensors finality, and not its implementation (which is considered in the *Sensor* mediator). Example members of this family are the *Temperature\_Sentient* and the *Light\_Sentient* components. These components implement not only transparent access for sensors, but also some functionalities such as unit conversion, threshold comparison of results, and data logging, which are mapped as configurable features or aspects. Once the application uses a member of the *Sentient* family, it is up to the EPOS framework composition rules to maintain the sensing sub-system coherence, by granting that, for example, the *Temperature\_Sentient* abstraction will use an available temperature *Sensor* mediator. This is ensured by the system configuration and generation process, which takes into account the application analysis results and the hardware platform description [15].

## 5 Evaluation

In order to test the expressibility, portability and cost of the EPOS sensing subsystem, we implemented a simple sensing application using three different operating systems: TinyOS, Mantis e EPOS. The application in question implements a loop that constantly reads data from a sensor and redirects the data read to a UART interface. Whenever it was necessary to implement architecture-dependent code, the Berkeley Mica2 mote [8] was considered as the target platform. In order to better compare the overhead in the different implementations, the applications used the least possible operating system resources. Figure 4 presents the implementation of this application for the three analyzed operating systems.

The application for TinyOS was written in the NesC programming language, and its implementation consists simply in connecting inputs and outputs of interfaces (ADC and UART, in this particular case). Had it been necessary, the implementation of algorithms could be done in NesC, with *C-like* syntax. The application for Mantis was implemented in C, including the headers defining Mantis's device access and communication APIs. The application for EPOS was implemented in C++, importing the sensing abstraction and the UART mediator headers.

In the Mica2 platform, the TinyOS system reflects the hardware design and exports the temperature sensor as an ADC (in the physical platform this sensor is analog and is connected to the micro-controllers ADC). This dependency between hardware and operating system will certainly bring implications to the application portability when, for example, it is ported to a platform in which the temperature sensor is digital and is connected directly to

```

/* TinyOS Sensing Application */
configuration SenseToUART {}
implementation {
  components Main, SenseToInt, IntToUART, TimerC, DemoSensorC as Sensor;
  Main.StdControl -> SenseToInt;
  Main.StdControl -> IntToUART;
  SenseToInt.Timer -> TimerC.Timer[unique("Timer")];
  SenseToInt.TimerControl -> TimerC;
  SenseToInt.ADC -> Sensor;
  SenseToInt.ADCControl -> Sensor;
  SenseToInt.IntOutput -> IntToUART;
}

```

```

/* Mantis Sensing Application */
#include <inttypes.h>
#include "led.h"
#include "dev.h"
#include "com.h"
static comBuf send_pkt;
void start (void) {
  send_pkt.size=1;
  while(1) {
    dev_read(DEV_MICA2_TEMP, &send_pkt.data[0],1);
    com_send(IFACE_SERIAL, &send_pkt);
  }
}

```

```

/* EPOS Sensing Application */

#include <sentient.h>
#include <uart.h>

Temperature_Sentient t;
UART u;

int main()
{
  while(1)
    u.send_byte(t.read());
}

```

**Figure 4. Sample sensing applications**

microcontroller IO pins. Even if the application functionality remains the same, it will have to be altered taking into account the details of the hardware platform in which it will be executed.

A similar problem occurs in the implementation for the Mantis operating system. The temperature sensor is read through a device access function, which takes as a parameter the physical device the application wishes to read. Evidently the physical sensor model may vary from platform to platform, and the application will not be portable between different platforms, even when it maintains the same functionality. This problem could be partially solved in the Mantis system by indicating through a series of define statements that would indicate that, for example, in the Mica platform, the `Temperature_Sensor` symbol denotes `DEV_MICA2_TEMP`. Nevertheless, this would still be an inefficient and inelegant solution, as the `dev_read` method aggregates code for the reading of every device available in the platform, even when some of them are not used by the application.

The implementation for the EPOS system does not present any dependency to the target hardware, except for the requirement of an available temperature sensor, and is perfectly portable between platforms that satisfy this requirement. The selection of hardware mediators is resolved by the system framework, taking into consideration the interfaces used by the application and the target platform specified by the programmer.

Table 2 presents the code and data sizes for the three generated applications. The EPOS system presented the

smallest cost in bytes between the three test systems, for both data memory and code size.

	Mantis	TinyOS	EPOS
.text (bytes)	22486	9990	5522
.data (bytes)	74	16	22
.bss (bytes)	711	358	152

**Table 2. Generated application sizes**

Evidently, an evaluation based simply in program code and data sizes is incomplete, but in resource-limited systems such as sensor nodes, these values are of uttermost importance. Future evaluations of this work will include performance and energy-consumption measurements.

## 6 Conclusions

We discussed the problem of heterogeneity in sensor networks hardware, and presented a novel technique to handle application portability in these systems. We used the concepts of *hardware mediators* and *system abstractions* to model and implement the EPOS sensing subsystem, which allows sensing applications to be ported between different sensor networks hardware platforms. A sample sensing application was implemented for the EPOS operating system, as well for other available operating systems for sensor networks. The EPOS system presented

the smallest size in terms of code and data size. These results position EPOS as a very viable alternative for operating systems for sensing devices.
